Abstract

David Ricardo's idea that market prices fluctuate around natural prices, and that natural prices are determined by the labour requirements producing that commodity will be tested using data for period 1951 to 2000 Japan. The natural price of Ricardo's writings are usually considered as production prices. However, determination of normative general profit rate is rather ambiguous and general profit rates are usually determined as ex-post average profit rates of all industries, where average profit rates are very close to zero and profit rates are sometimes negative in recent years of Japan. In such economic performances, positive general profit rates do not have positive and normative justification. Therefore, value relative prices (general profit rates taken as zero) are taken as natural prices and it will be compared to market prices in the following.

Findings indicate that there are gradual tendency for the market prices to converge towards value relative prices. There are problem with Japanese agriculture, and slight diverging movements in 1970, however the movements of metal and manufacturing industries indicate significant and clear movements of market prices towards value relative prices over 50 years. There are tendency that profitable industry at profitable period to diverge from such trend, however with free entry and free exit such movements donot hold for long period.

Comments on Revision

This is a revision of my last work which I presented in the Turkey meeting of this IIOA. Major revised points are on labour data. Data on persons engaged in production in agriculture is revised. There is another stream of data on core number of persons engaged in production in agriculture, which is smaller than current data that I have employed here, provided by the Statistical Office of Japan based on Population Census. This stream of data will give results that market prices are much more closer to value relative prices. However, as a time series stream of inter-medium data, I followed RIETI data provided by the Ministry of Economics and Industry. This revision is giving agricultural market prices a little diverging from value relative prices but not so much as the first estimation presented in Turkey in year 2007.

Capital depreciations are taken into account only as fixed cost, and was not dispersed to each industries as depreciation coefficients. Further revision on this point may require investigation, however this simplification is expected that it will not influence the trend.

Capital cost other than depreciation is neglected, or the general rate of profits are taken as zero. Opportunity cost of interests may have thought of to replace general rates of profit, however opportunity cost as deposit interest rates vary over time, from around 6 % to 0%. After the recession of 1992, the deposit interest rates in Japan are negligible and are very close to 0% (0.005% for year 2000). Taking into account of this historical reality, I thought there are not clear reasoning what the level of general rates of profit should be. According to these variety of profit rates over years (or different deposit interest rates over years), rate of profits as equal to 0% are taken as standard for time series comparison.

When wages are payed in advance and profit rates are uniform as general profit rates, prices are denoted as

$$P = (1+r)(wl + PA + PD)$$

where the last term denotes depreciation costs. **D** denotes depreciation coefficient matrix.

$$P = (1+r)(wl)(I - (1+r)(A + D))^{-1}$$

Total labour requirements (labor value) are

$$t = l + t(A + D)$$

$$t = l(I - (A + D))^{-1}$$

Therefore, while wages are paid ex ante, and wages and profits are uniform over sectors, prices of production are relative to values when profit rate is equal to zero.

That is, my comparison of market prices to value relative prices includes two components. The first component is the difference between the market prices to prices of production, and the latter is the differences between the prices of production to the value relative prices. The latter depends on the size of general rate of profits, while the former depends on the differences of realized sectoral rate of profits to the general rate of profits, and the difference of actual wage to the average income per persons engaged in production.

David Ricardo thought that market price fluctuates around natural prices, and that natural prices are regulated by the total labor requirements of commodities. That is, total labor required to produce that commodity (total labor requirements) determine the value of that commodity, and that relative prices are determined by its value. This paper tries to examine this discourse using data from input output tables, RIETI labor statistics of Japan. RIETI labor tables are integrated into 32 sectors. Market prices and natural prices for outputs of 32 industries of Japan for years 1951 to 2000 were calculated.

Findings are as follows. (i) When all industries other than agriculture are taken into consideration, market prices converge towards natural prices. (ii) When narrowly defined manufacturing industries,

mainly machineries only are taken into account, market prices converge towards natural prices. These movements may be explained by international competition of free entry and exit as machineries are traded goods and also by the standardized wage negotiation process of manufacturing sectors, especially of machineries. (iii) Profitable industries at profitable periods diverge from natural prices.

There are yet more room for improvements in data, and methodology (treatment of depreciation and capital). However it may be possible to conclude that where there are competition both in commodity market and in factor market, there are tendency for the market prices of output to converge towards value relative prices.

There are stream of works on the determination of prices. While many economists emphasize demand and supply to determine market prices, there are some economists that think that there are some theoretical movements behind market prices.

David Ricardo in his book of “Principle of Political Economy and Taxation” analyzes as follow. Value of commodity is determined by the amount of labor bestowed to produce such a commodity. Natural prices are prices determined relative to such value, and market prices accidentally digress from such prices. However, prices are in a long run determined by natural prices.

My question is, if there are any theoretical movements behind the market prices in the long run. In the long run, there are competition among firms, output markets, intermediate markets, and also in the factor markets. How and where do these competition lead the market prices? This is the question to be asked, and in the following I will construct natural prices (value relative prices) and compare the market prices to value relative prices.

2 Calculation of Labor Value (Total Labor Requirements).

I wish to explain about the method of calculation of labor value or total labor requirements. Labor Value equivalent to total labor requirements are considered as labor bestowed to produce the commodity. Let us denote the total labor requirements of each industry by t_j and its vector by row vector \mathbf{t} . When a_{ij} is the ij factor of input output coefficient matrix \mathbf{A} and l_j is the direct labor coefficient of industry j , total labor requirement is obtained by direct labor coefficient vector \mathbf{l} post multiplied by Leontief Inverse.

$$t = l(I - A)^{-1}$$

This can be explained in two ways. Leontief thought that in order to produce one unit of commodity of each sector it is necessary to produce one unit times Leontief inverse. Therefore, the labor required to produce one net product are net product times Leontief inverse times labor coefficients.

The same equation can be interpreted as equations solving simultaneous equation of n unknowns of total labor requirements. When total labor requirements of sector j is denoted by t_j , row vector of total labor requirements t can be solved as sum of total labor contained in intermediate inputs plus direct labor requirements.

$$t = tA + l$$

$$t = l(I - A)^{-1}$$

Above solution needs further improvements when applied to real calculation. One problem is depreciation of capital, and another is calculation of imported inputs.

Depreciation of Capital

Capital is always the most problematic issue in input output analysis as input output tables are flow tables. If capital formation table is available, depreciation allowance of each sector can be proportioned to each industry supplying capital goods. That is, the depreciation allowance of sector j denoted by Z_j are allocated (proportioned) to each industry of origin as

$$d_{ij} = \frac{K_{ij}}{\sum_i K_{ij}} \frac{Z_j}{X_j}$$

Where K_{ij} is the i component of j industry's capital formation obtained from the capital formation table. X_j is the total output of j industry. Therefore d_{ij} denotes the i depreciation coefficient of industry j.

Then the equations to obtain total labor requirements are modified as

$$t = t(A + D) + l$$

$$t = l(I - A - D)^{-1}$$

where D denotes depreciation coefficients matrix.

Import and Export

Treatment of imported commodity may have several ways. One way is to treat all imports as competitive and treat imported commodity exactly as domestically produced products. However results of this treatment did not give good results for Japan. Let us call this treatment as ultra fair trade model. As Japan highly depends on imports of energy, prices of energy related imports requires much higher value relative prices by this replacements.

The (labor) value of imported inputs are unknown. In order to determine the unknown value, a method to replace the imported value by the labor value contended in the same monetary value of exports to purchase the imported inputs is developed in Japanese tradition (). This does not necessarily assume balance in the current account of balance of payments, however any purchase are eventually paid (it might be paid by capital return or transfer but as input output analysis does not assume intertemporal equilibrium and so time is not included in the analysis, concept that requires different time horizon are neglected.) Let us assume that in order to purchase imported inputs, tradables (exportables) are produced. Labor value of imported inputs are replaced by the labor value of average export times the monetary value of imported inputs. By denoting average export components by vector e' , and row vector of imported inputs by m , the labor value of unit import which is denoted by t^m must equal te' (multiplication of each average export contents by its total labor requirements).

Then the equations of total labor value are modified as,

$$t = t(A^d + D) + t^m m + l$$

$$t^m = te'$$

By inserting the second equation the first equation gives,

$$t = t(A^d + D) + te' m + l$$

This can be solved as

$$t = l(I - A^d - D - e'm)^{-1}$$

Export component vector are calculated as $e_j = \frac{e_j}{\sum_j e_j}$ and therefore

$$\sum_j e_j = 1$$

Domestically produced input output coefficients are calculated as the proportion of total output to domestic products using the proportion from the final demands. That is, taking the proportion of total imports

$$\text{to total output as } \mu, a_{ij}^d = \frac{1}{1 + \mu} a_{ij} = \frac{1}{1 + \frac{M_i}{X_i}} a_{ij}$$

Therefore, import coefficients can also be calculated as

$$a_{ij}^m = \frac{\mu}{1 + \mu} a_{ij} = \frac{\frac{M_i}{X_i}}{1 + \frac{M_i}{X_i}} a_{ij}$$

Then,

$$m_j = \sum_i a_{ij}^m$$

Import coefficient vector is a row vector of these total imports for sector j, denoted by m_j s.

3. Natural prices (Value relative prices)

The prices that equalizes the income of all labor participated in production are prices which are equal to total labor requirements. The two sets of prices are identical. It can be proved as follows.

By denoting the labor value of commodity as total labor requirements by t,

$$t = l(I - A^d - D - e'm)^{-1}$$

The natural prices of commodities must fulfill the following

$$\frac{p_j}{p_i} = \frac{t_j}{t_i}$$

Assuming

$p_i = \lambda t_i$ holds for any i , then,

$$p = \lambda t = \lambda(I - A^d - D - e'm)^{-1}$$

Rewriting gives,

$$p(I - A^d - D - e'm) = \lambda t$$

That is,

$$p = p(A^d + D + e'm) + \lambda t$$

Therefore, return for all labor is equal. (Value added per labor are all equal among all sectors.) That is, natural price are prices that give equal return to all labor in production in all sectors. And that lambda should equal to average income per persons engaged in production.

In reality, set of natural prices were obtained as prices that will achieve equal return to all labor participated in production as follows due to resources constraint. That is, natural prices row vector p are calculated as prices that achieve

$$p = pA + d + y^*l$$

Where y^* is average income per labor participated in production (scalar). Depreciation matrix was not obtained, depreciation per output of each industry were added to price equation as vector d . Components of d vector is Z_j/X_j for every industry j . Solution of the above equation is obtained by solving n simultaneous equations

$$p = (y^*l + d)(I - A)^{-1}$$

However, as I mentioned earlier, this treatment of import and export did not give good result for mineral and oil related industries. Therefore, the calculation was based on the equations that converts the imported

value by the total labor requirements embodied in the same monetary value of exports

$$p = pA^d + p e' m + d + y * l$$

Therefore the solution was obtained as

$$p = (y * l + d)(I - A^d - e' m)^{-1}$$

This solution is called as natural prices obtained from program. N simultaneous equations (32 simultaneous equations) were solved. Row vector of the sum of average labor remunerations plus depreciation cost per output taken as fixed cost is post multiplied by the import/export modified Leontief Inverse Matrix.

The transaction table was integrated into 32 sectors for 1951 to 1980, while 32 sector transaction tables were available for 1990 and 2000. Data on labor coefficients were obtained from RIETI labor table for 1970, 1980, 1990, 2000. It is obtained from supporting table for 1960. It is obtained from various tables, both population census and labor statistics for 1951.

The following might be repetition of what I wrote earlier, however, I wish to clarify the idea of measuring the gap between the market price and the natural prices (value relative prices). Natural price of time 1 is different from natural price of time 2. Market prices are normalized to 1 for all sectors for all periods. The ratio between 1 and natural prices, or the difference between 1 and natural prices measure the difference between the market price and natural prices of each period.

When there are discrepancy between demand and supply, the gap will be adjusted either by prices, or by quantities. Price adjustments are called as Walrasian adjustment and quantity adjustment are called Marshallian adjustments. The purpose of this paper is not to show the speed of market price adjustments between equilibrium market price and the distorted real prices. The differences that are measured are the difference between natural prices and the real market prices. Real export market prices are subject to different degree of monopoly or oligopoly, increasing returns, different degree of market shares, different degree of factor market distortions, and other institutional constraints. The aim of following findings are to clarify if there are

tendency of natural (value relative prices) to show the trends of market prices or not.

4. EMPIRICAL RESULTS

Market prices are normalized as 1 for each sector for each period. Difference of market price and natural prices (value relative prices) can be measured by obtaining standard deviation of the two. From calculating standard deviation of natural prices minus market price (value relative price minus 1), all industries show 0.32 (1951), 0.33(1960), 0.38(1970), 0.35(1980), 0.35(1990) and 0.35(2000) as standard deviation. If agriculture is deleted, the standard deviation becomes 0.23(1951), 0.24(1960), 0.27(1970), 0.23(1980), 0.23(1990) and 0.25(2000) on revised data. Therefore there are tendency for the value relative prices to converge towards market prices (other than 1970) for all industries other than agriculture. Or, at the time of boom, there are slight tendency for the standard deviation to increase its value.

Reclassification of service sectors of input output tables took place in 1985, and therefore direct labor data requires another check for service sectors especially for personal services, business services, and other public services. There are activity such as machinery maintenance or repair which was included in the machinery sector before the reclassification, which are included in business service after the reclassification. This change cannot be treated as number of labor associated this activity before 1985 cannot be counted. Such limitation should be kept in mind.

From the overall movements for 1951 to 2000, there are quite clear trend that market prices are converging towards value relative prices. The gap between market prices and value relative prices are decreasing over time.

The only exception is agriculture for all the periods. The noticed movement against these trends (diverging from these trends) are, communication (1990-2000), transport machinery (1970s), iron and steel, and general machinery (1980s). These may be explained as the period that these industries are highly profitable but free entry to these industries were yet limited or difficult.

The market prices of oil and coal and electricity stay high compared to value relative prices. These are industries where market forces do not work as these are highly protected, monopoly or oligopoly, or regional monopoly except coal.

Even for highly profitable industries as finance and insurance and real estate, market prices are very slowly moving (lowering) towards value relative prices.

Manufacturing industries can be classified to two groups. Value relative prices of light manufactured industries had been higher than market prices. That is, market prices of light manufacturing industries increased toward value relative prices. On the other hand, market prices of heavy industries had been higher than value relative prices. That is, market prices of heavy manufacturing industries had been declining towards value relative prices. Such movements are very clear with industries 8 to 15, metal related machinery industries. This is one of the most clear and significant finding of this study.

Food processing, textile and commerce require increasing of efficiency or increase of market prices towards value relative prices.

More efficiency is required, or even exit from the market might be required in light industries which face low international output prices. Also in commerce, recent construction industry (2000), and personal services need more efficiency. Elderly care also requires revision or restructuring of industry.

More free entry is required in oil plus coal, mining, water, electricity plus energy supply, finance plus insurance and real estate. Output prices of these industries should become lower.

Detailed observation by industrial groups.

From agriculture to oil and coal products

Agriculture Agricultural market prices are diverging from value relative prices. The gap between the market prices and value relative prices are about 2.5. Production of agricultural output for home consumption might require revision of output data. (income or output data might need to be re-estimated to include these home production).

Oil and coal products. Market prices of this industry remain low. The protected nature of this industry, oligopoly is apparent over time. However if we take ultra-fair trade model (import are taken as purely competitive), this sector's natural price becomes very high (about 3 times). That is, oil and coal products highly depend on imported intermediate inputs, and therefore if competitive assumption is taken, we have to pay very high natural prices=value relative prices.

Mining and Chemical Market prices of mining and chemical also remain low compared to value relative prices.

Food processing, textiles and pulp and pulp products Food processing, textiles and pulp plus pulp products converge toward value relative prices. Market prices are rising toward value relative prices.

Metal and Machinery (Industry 8 to 15)

The market prices of these industries are clearly converging towards value relative prices. The movements of these industries are so clearly “harmonious”. That is, the movements are clearly “together”. The output prices are clearly “lowering” towards value relative prices. The general price increase of these era (general GDP deflator is greater than these price increase, and the real growth of these industries (manufacturing) was greater than real GDP growth throughout the period with very few exceptions. The growth of these industries were transmitted to other industries in the development process of Japan.

The only exception of such price movements are, that is, market prices are increasing more than the value relative prices are transportation machinery of 1970s and iron, steel and general machinery of 1980s. These periods can be noticed as periods that these industries were the leading industry of each period.

For metal and machinery industries, the economy was moving towards perfect competition, and that the economy was shifting towards realizing free entry and free exit. In the machinery industry where increasing return may work, free entry and free exit are limited. Besides, life time employment was apparent in Japan until recent, which could have created wage differential among industries. However, uniform negotiation process such as IMF-JC lead wage negotiation created very equal income structure for the manufacturing sectors. Manufactured goods was traded goods facing international competition made output markets to operate as perfect competitive markets.

Service Related Industries

Movements of eight industries in this group are somewhat complex. General tendency is that market prices are converging towards value prices.

Commerce indicates a little exceptional movement, especially for years 1980 to 2000. Market prices remained low compared to value relative prices, either reflecting the inefficiency of this industry, or the keen competition of this industry faced to the international competition after mid 1980s which lowered the output price.

Communication is another exception that market prices are digressing from the value relative prices, especially from the 1980s. Market prices are higher than value relative prices and the gap is increasing from 1980s. This industry is realizing high profit throughout the period.

Market prices of construction fluctuate around the value relative prices. Market price starts from the point that per income of construction labor are higher than the economy's average. Construction achieves high income per labor in the 1990s, but it turned down in the 2000s after the burst of the bubble economy in 1992.

Prices of water and waste is decided in local congress. There are considerable lowering of market price of water and waste towards value relative prices in the 1970s. This reflects that the price adjustment delayed or was sluggish to the inflation of the 1970s. The GDP deflator increase was 13.4% in 1973 and 19.8% in 1974. And yet, water which is supplied by regional monopoly, and waste are achieving market prices that yields high per labor income compared to the whole economy.

Transportation as service industry shows clear well fitted convergence of market price and value relative prices.

Electricity, gas and energy supply remain high market price as these are highly protected regional monopoly prices.

Finance and insurance also remain high market prices, but there are slow tendency to converge towards value relative prices. Market prices move towards value relative prices especially in 1980s and 1990s. 1990s deregulation (big bang) might have worked, but there are slight digression in 2000 data.

Real estate also remain high market prices, but the trend is that the market prices are converging towards value relative prices. The gap is big, but there are slow trend to converge.

Services

Education and public sector may require a little lower output prices, lower income per labor after 1980s. Religious activity was excluded from this sector to other public services for 1951.

Medical service includes elderly care recently after 1985. For this reason, the high income nature of this industry was obscured after 1980s.

Business service shows good convergence of market prices and value relative prices.

Personal services requires higher market prices. It is likely that the labor of this sector are lowly paid.

Other public sector Output data doesnot exit for 1951. The output data for 1970 doesnot coincide with labor data.

Unclassified All the discrepancies are accumulated into this sector. Reclassification of labor data are essential for these industries.

5. CONCUSION

This was my second trial to construct value relative prices and to analyze the movements between actual market prices for 50 years.

Exceptions exist such as the movements of agricultural sector, or the movements between 1960 to 1970, or profitable sector such as communication of 1990s and 2000s, leading sectors of 1970s (transport machinery) and 1980s (iron, steel and general machinery), however, I think it is approved to state that there are tendency for the market prices to converge towards value relative prices. This tendency was clearly apparent for metal and machinery related manufactured industries.

Although labour market remained non competitive for Japanese market (life time employment for large firms), opening of output markets and facing international competition were leading forces for the metal and machinery industry to set market prices close to value relative prices, and also to keep profits rates low. Service sectors outputs of which are non-tradables require more competition, and agriculture requires revision of its industrial structure most sseriously.

Market forces, international competition, and united labor movements existed to achieve equality among industries especially in metal and manufacturing sectors. Equality between industries does not necessarily result in equality among person to person income (and moreover asset) distribution. The fact that personal income distribution after the burst of the bubble economy (year 1992) is worsening in Japan (especially for the asset and for the aged); equality among industries did not necessarily guarantee the inter-personal income equality should be kept in mind.
