¹ Visiting scholar at Bournemouth University, United Kingdom and at Shanghai University of International Business and Economic, China. Associate researcher Aix-Marseille School of Economics France. Former WTO Chief Statistician and UN-ECLAC Director. Contact email: hubert.escaith@outlook.com
I thank Y. Shiozawa, L. Zhang and H. Xu for helpful comments when preparing the research project and E. Drevinskas for explaining some obscure features of the R language. All errors and omissions are my sole responsibility.

This research was initiated when visiting the School of Trade Negotiations, Shanghai University of International Business and Economics, in November 2018. I wish to thank its staff and faculty for providing a propitious research environment.

1. Introduction

A new production and trade business model arose in the late 1980's, based on the geographical fragmentation of complex production processes. In this process, trade in intermediate goods grew in importance, increasing economic interdependency within the World economy.

This submission to the IIOA presents a new approach that builds on input-output and trade analysis to derive plausible scenarios. The approach was developed following the *Keep It Super Simple* (KISS) design principle; the R program is made available in annex. The method remains exploratory, it offers a series of “markers” corresponding to extreme or expected situations that should help mapping what remain largely uncharted waters: the direct and indirect effects of bilateral trade conflicts on global production networks. Despite its simplicity, it is able to reproduce several of the steps actually observed in previous trade conflicts involving two large economies. It can also be used to generate “*in silicio*” large data sets of numerical “observations” of the mode of insertion of industries and countries in the international market that can be further analysed using appropriate statistical techniques.

The paper counts with three parts, besides introduction and conclusion. The first one is theoretical, including a review of the literature and a formal exposition of the methodology, starting with the presentation of a formal model of inter-industry trade before describing the empirical application to input-output analysis. The second is didactic, applying the method to a small six-countries/three-industries model designed to mimic inter-industry interactions between hypothetical trade partners with different comparative advantages. The third part applies the methodology to the bilateral trade conflict that arose between China and the USA in 2018, using the WIOD database. It presents the spill-over effects on third countries through international supply chains and export restructuring. Applying exploratory data statistical analysis to the results obtained by simulating a series of bilateral shocks, the paper shows how the method can also be used for generating analytical data and identify modes of insertion in the global economy.

2. Formal and Empirical Models

Before looking at the actual results of the extraction-cum-substitution simulation, it is worth considering a more conceptual approach that shows how GVC trade changed the traditional way of looking at international trade and comparative/competitive advantages. Trade theories struggled to adapt to a world where countries trade in intermediate inputs. Their answers help understanding why the spill-over and retroactive effects of a bilateral trade conflicts are much more complex than was previously understood in traditional models where trade takes place in final goods.

1. Theoretical Model of GVC Trade

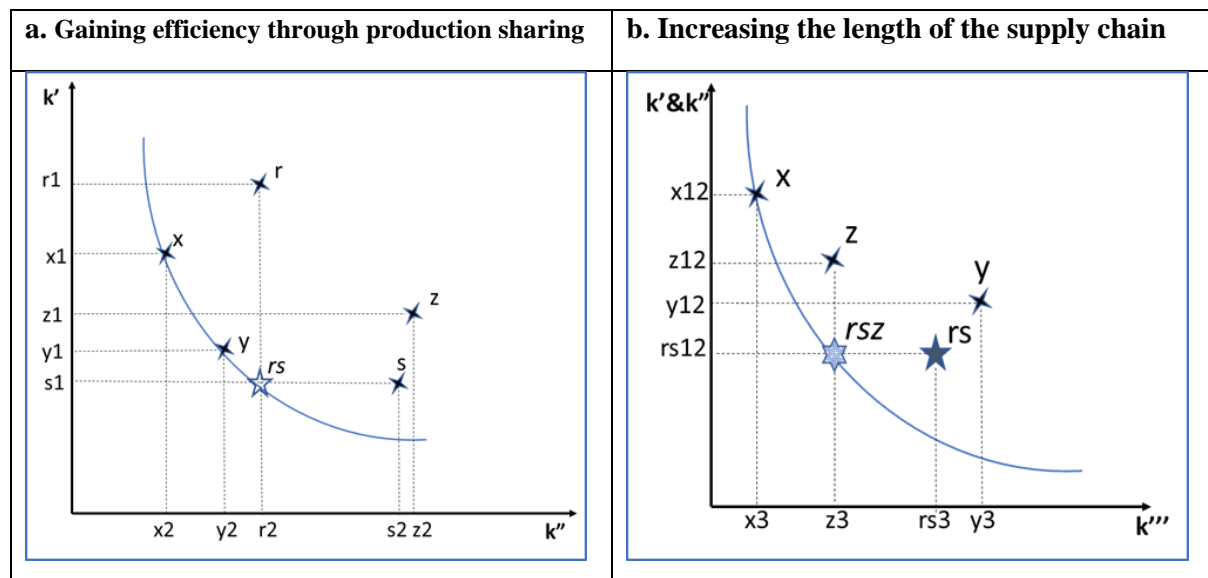

When firms belong to a geographically fragmented production network, what they actually trade is not intermediate goods –even if this is the visible trade flow that crosses borders-- but the value-added

they are able to create and incorporate into these products. This is reason why this type of business-to-business (B2B) trade is known as “GVC trade”, “trade in tasks” or “trade in value-added”. Mapping and measuring this new type of trade in value-added has led to the definition of new empirical methodology. But it also required adapting the theoretical models that had explained trade since the 19th century, because those models were not describing satisfactorily the logic of comparative advantages when trade in intermediate inputs is pervasive (Grossman and Rossi-Hansberg, 2006).

Indeed, in the traditional Ricardo or Heckscher-Ohlin models, comparative advantages are somewhat “natural” and come from the unequal distribution of primary production factors such as land, labour and capital. In a global value chain, what the lead-firm (the firm which is the main driver of the upstream supply chain and the down-stream sales to the final users) looks for is creating value by selecting the best suppliers of the required tasks –research and development, design, production, logistics and distribution—on a worldwide basis. In this process, comparative advantages from the lead-firm perspective are “created” instead of “natural”, because they may not correspond to the factor endowment of the lead-firm country.

An intuitive way of looking at the competitive gains through GVC is to borrow from Efficiency Frontier Analysis using Data Envelopment Analysis (DEA), a branch of Operational Research (see Cooper et al, 2011, for a review). At the difference of standard DEA, in this case the prices of non-tradable differ from country to country. Figure 1 shows on a diagram how two inefficient producers in two different countries can join forces and become internationally competitive. The diagram in panel (a) depicts the relative efficiency of five production units (r, s, x, y, z) located in different countries, and using two inputs to produce a variety of similar goods: the first input is produced with a technology k' intensive in labour and the second one (based on k'' technology) is intensive in technology. The r firm is located in country A while s is in country B. Other firms are located in various countries in the Rest of the World.

Figure 1 Gaining efficiency through production sharing

Note: k' : use of intermediate input based on labour intensive technology to produce q_0 ; k'' : use of capital-intensive input; k''' : use of natural resource intensive input.

Under frictionless free market, all physical inputs and outputs are priced the same, but firms face different labour wage rates w . An additional hypothesis is that, following the Balassa–Samuelson effect, the higher the technological level of the country, the higher the unit cost of labour. In other words, advanced industrial countries pay higher wages than developing and emerging countries.

The isoquant shows the minimum combination of inputs to produce a given quantity of good q_0 (we look here at a mix of technical efficiency and allocative (price) efficiency through the minimization of the value of inputs used for producing a fixed level of output).

In a traditional Efficiency Frontier Analysis, the isocost line would be a straight line, because the unit cost of input produced by k' and k'' would be the same for all firms. In our case, the isocost line is curved and blends with an isoquant because the price of labour is supposed to be inversely proportional to the technology level attained by countries. For the sake of simplicity, we assume that all firms that are technically efficient are also price efficient (overall efficiency).

Out of the five firms in panel a of Figure 1, two (x, y) are on the isoquant and are competitive at world price. Three firms (r, s, z) are away from the curve and inefficient for this production technique. Yet, r inefficiency (called a slack in Frontier Analysis) relates mainly to its use of input produced using k' technology, while s is inefficient mainly for input of the k'' type. The comparison of slacks is clearer when we measure it as the “city block” metric, i.e. the sum of the horizontal and the vertical segments from r or s to the isoquant. If it is possible to separate the production of intermediate inputs of type k' and k'' in two separate steps, then unbundling the production of q_0 in two components allows r to specialise in the production of the components intensive in input of k'' type, while s specialises in the tasks that are labour intensive (technology k').

Because slacks are independent of each other by construction of the data envelopment technique defining the efficiency frontier, the unbundling maintains the efficiency of each firm for each zero-slack input (s_1 and r_2) and creates a new virtual firm rs that is now cost efficient and located on the isoquant.² Production of the final good q will be physically located in s , the country efficient in the labour-intensive inputs (labour being not tradable).

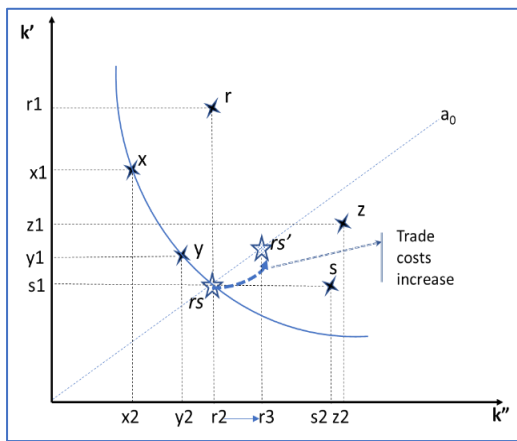

On the other hand, inefficient firm z cannot use the GVC business model, due to its relative inefficiency in the use of both inputs (panel a). But a production technique requires many different inputs, and z may be efficient in the use of another component required for producing q_0 . In panel b, the vertical axis is now a projection of the isoquant in panel a, and represents the mix of efficient use of inputs of k' and k'' type (note that the origin of the axis is not 0 anymore but the horizontal asymptote of the isoquant in panel a). The horizontal axis represents another type of inputs, for example one that requires a technology k''' that is intensive in natural resources. Only one firm, x , is on the new isoquant, when all three inputs are taken into consideration. But the joint-venture rs can now become cost-competitive by incorporating z into the value-chain, sharing production in order to move to the new production unit rsz , on the isoquant. Production of the final good q will remain located in the country of s , the country with the efficient use of the labour-intensive input.

² Input slacks are the input reduction required to reach efficiency. They are associated with the constraints associated with the optimal solution of the input minimization linear program used to define the efficiency frontier in DEA. These constraints are mutually independent in the optimization model.

What happens when bilateral trade costs between r and s increase, due to the imposition of prohibitive trade barriers between country A and B? The world price of the final good q_0 does not change because it is efficiently produced by x and can be freely imported by s and r countries. But the initial joint-venture between r and s is no more cost-efficient, as pictured in Figure 2. Due to bilateral trade barriers, the cost of delivering r intermediate inputs to s increases, and r cost-efficiency moves from r_2 to r_3 . Because of the trade barriers, the cost of producing the bundled q_0 goods for the joint-venture moves away from the origin and the isoquant, along the line a_0 . At rs' , the joint-venture is no more competitive and the GVC arrangements breaks-up, causing mutual damages to r and to s .

The disruption will also affect firm z . This is a spill-over effect of the trade conflict between the countries where r and s are located. Due to this bilateral trade conflict, the rsz joint-venture is no more profitable at international process and exits the market. Only one firm (x) remains competitive at free trade final good price.³

Figure 2 Losing GVC efficiency due to trade barriers

Note: see Figure 1

This bilateral trade conflict diverts trade patterns away from their comparative advantages and impedes the specialization in tasks which was beneficial for the three countries involved.

What if A initiated the trade conflict and r , the lead-firm located in country A, re-imported the finished product for sales on its home market or exported it to third markets? Disrupting the rs supply-chain increases the cost of procuring intermediate inputs and lower A's competitiveness on both its home and export markets (the case analysed in Figure 2). The unexpected end-result may be for A to exit this market if the related increase in production costs turns the production unprofitable at current prices. So, if the trade conflict between A and B was the shift of labour from country A to country B, because the s firm located in B is more competitive in the labour-intensive intermediate input, the end result of the trade war may be worst for A than the GVC option, because it will also lose the jobs that

³ This discussion applies only when the surge in trade costs is bilateral and does not affect the price of the final good. If A wants to raise the Home market price of the imported final good irrespective of its origin, country A needs to raise trade costs with all trade partners. Firm r would then be able to compete with its foreign competitors, but will be profitable only at the inflated price in its Home market. We recognise here the anti-export bias of trade costs and protectionist policies, see Escaith (2017) for an analysis when GVC trade is prevalent.

were related to production of the capital-intensive intermediate input produced by r for the rs joint-venture.

This is not a purely theoretical outcome: estimating the outcome of the NAFTA demise, Walmsley and Minor (2017) show, using CGE models, that the US automotive industry –the same one which was expected to be protected from the competition of other NAFTA producers– could suffer from negative side effects. The production of light passenger cars would be reduced due to the loss of competitively priced parts imported from Mexico and the resulting decline in the competitiveness of US producers on export markets.

A formal treatment of this process can be derived from Shiozawa (2007) and Shiozawa and Fujimoto (2018), who push forward the reinterpretation of the Ricardian model away from the general equilibrium strand, adding micro-foundations that can be traced to the work of Sraffa (1960). Looking for an optimal trade and production pattern from the supply side of the economy, they define for each country the domain of (i) technically feasible and (ii) comparatively efficient with respect to other trade partners' production functions.

Their Neo-Ricardian model and its cost-of-production based theory is also particularly relevant for our empirical research on trade in value-added, because it has an almost one-for-one counterpart with International Input-Output modelling. In input-output modelling, the final demand side is also considered exogenous to the model and the focus of attention is on the supply-side, in particular on the role of inter-industry linkages, as described in Figure 3.

Figure 3 International Input-Output matrix

Outputs		Intermediate Use				Final Demand				Total Output
		1	2	...	M=kxn	1	2	...	M	
Intermediate Inputs	1	Z^{11}	Z^{12}	...	Z^{1m}	Y^{11}	Y^{12}	...	Y^{1m}	X^1
	2	Z^{21}	Z^{22}	...	Z^{2m}	Y^{21}	Y^{22}	...	Y^{2m}	X^2
	
	M	Z^{m1}	Z^{m2}	...	Z^{mm}	Y^{m1}	Y^{m2}	...	Y^{mm}	X^m
Value-added		$(VA^1)'$	$(VA^2)'$...	$(VA^m)'$					
Total output		$(X^1)'$	$(X^2)'$...	$(X^m)'$					

Notes: Z^{sr} is an $k \times k$ matrix of intermediate input flows that are produced in country s and used in country r , k being the number of activity sectors (goods and services) and n the number of countries; Y^{sr} is an $k \times 1$ vector giving final products produced in country s and consumed in country r ; X^s is also an $k \times 1$ vector giving gross outputs in country s ; and VA^s denotes an $k \times 1$ vector of direct value added in country s .

Source: Adapted from Wang, Wei and Zhu (2013)

Formulated from an international perspective, there are N countries and K traded products, each product being identified with one industry. Following the notation in Shiozawa (2017) as much as possible, the formal model can be written as: ⁴

$$\mathbf{p} = (1+r) [(\mathbf{w} \cdot \mathbf{a}_0) + \mathbf{A} \mathbf{p}] \quad \text{Equation 1}$$

With

p: the price vector (of dimension K, K being the number of products/industries)

r: rate of net profit, assumed to be identical across industries and countries.

w: vector of countries' wage rates

a₀: vector of labour input coefficients

A: the matrix of intermediate input coefficients (the Z_{ij} intermediate input flows divided by the corresponding output X_j)

Under the usual conditions of $(\mathbf{I}-\mathbf{A})^{-1}$ existence in input-output analysis, this equation can be written:

$$\mathbf{p} = \mathbf{w} (1+r) \mathbf{a}_0 [\mathbf{I} - (1+r)\mathbf{A}]^{-1} \quad \text{Equation 2}$$

Equation [2] relates the real rates of profit and wage in a long-term situation where the economy is at full capacity and budgetary constraints are binding (consumption must be paid out of wages and gross investment out of savings). ⁵ In the tradition of mark-up pricing, the factory-gate price is fixed by multiplying the full production cost (including wages) by a pre-determined rate, or mark-up. In a situation of frictionless trade, the price of a traded product is equal across countries.

Labour within each country is assumed homogeneous, but may differ across countries; there is no international movement of labour forces. The wage rate for country "k" is uniform across industries and denoted w_k . There are H different possible techniques. ⁶ A good can be produced by different processes/countries. The set of all production techniques applied to all (traded) goods is H x N. The essential point when technologies are widely available, as it is the case in today's globalised world, is the large difference of wage rates between countries.

This is an important feature when considering the issue from the "new" new trade theory that puts the emphasis on firms and not on countries. In agreement with this perspective, it is be wrong to state that "GVC involve several countries, where each economy has specialization in a stage of the production process" because countries do not actually trade, firms do. But countries have different wage rates for similar levels of skills, and –excluding trade costs and disparities in hard and soft infrastructure– this difference explains specialization in modern manufacturing supply chains.

The productive capacity of any country is determined by the quantity of labour and the set of feasible production techniques. Given these technology sets, there exists an international value where all firms

⁴ This section draws on Escaith and Miroudot (2016) and is based on reduced-form input-output models; it differs from other theoretical models, as in Shiozawa (2017), where each country exports a distinct variety of K products, leading to a total of N.K differentiated commodities.

⁵ Note that this inequality also holds when applying the analysis to an input-output framework. It becomes an identity when all income sources (wages and gross profit) are taken into consideration.

⁶ In a neo-classic approach "à la Armington", the differencing factors is not technology but goods produced by different countries and that are inherently imperfect substitutes by virtue of their provenance.

are (1) producing with the best production technique and (2) purchasing input products from the least cost providers (including price and trade costs).⁷

For example, let's consider two countries, A and B, and one product q . If trade takes place at no cost, the price of the two traded goods is the same in both countries. For one unit of output for product q , the material input coefficients for country A are $\mathbf{a}_+(\mathbf{k}^A)$ and the labour inputs $\mathbf{a}_0(\mathbf{k}^A)$. If \mathbf{k}^A is superior to \mathbf{k}^B for a given international value vector $\mathbf{v} = (\mathbf{w}, \mathbf{p})$, the following inequality holds:

$$\mathbf{a}_0(\mathbf{k}^A) \mathbf{w}(A) + (\mathbf{a}_+(\mathbf{k}^A), \mathbf{p}) < \mathbf{a}_0(\mathbf{k}^B) \mathbf{w}(B) + (\mathbf{a}_+(\mathbf{k}^B), \mathbf{p}) \quad \text{Equation 3}$$

If the possible set of production techniques are similar in A and B, a common feature of GVC where technology and know-how is directly or indirectly shared between GVC participating firms, the difference in competitiveness arises because of higher workers' productivity in A at the existing wage structure.

$$\mathbf{a}_0(\mathbf{k}^A) \mathbf{w}(A) < \mathbf{a}_0(\mathbf{k}^B) \mathbf{w}(B) \quad \text{Equation 4}$$

$$\mathbf{w}(A) / \mathbf{w}(B) < \mathbf{a}_0(\mathbf{k}^B) / \mathbf{a}_0(\mathbf{k}^A) \quad \text{Equation 5}$$

In order to mimic more precisely the inter-industry nature of GVC, Escaith and Miroudot (2016) split the production of good q into two production steps. Each of these two steps is operated a level $y(\mathbf{k}')$ and $y(\mathbf{k}'')$ and are part of subsets \mathbf{k}^A and \mathbf{k}^B . \mathbf{k}' and \mathbf{k}'' are producing complementary intermediate inputs that are not substitutable. For example, $y(\mathbf{k}')$ produces the body of a car, and $y(\mathbf{k}'')$ the engine. \mathbf{k}' is labour intensive, \mathbf{k}'' is technology intensive.

As long as Equation 6 holds for both \mathbf{k}' and \mathbf{k}'' , the car is produced entirely in country A. But if the relative productivities and/or wages change in such a way that:

$$\begin{aligned} \text{(i)} \quad & \mathbf{a}_0(\mathbf{k}'^A) \mathbf{w}(A) > \mathbf{a}_0(\mathbf{k}'^B) \mathbf{w}(B) \\ \text{(ii)} \quad & \mathbf{a}_0(\mathbf{k}''^A) \mathbf{w}(A) < \mathbf{a}_0(\mathbf{k}''^B) \mathbf{w}(B) \end{aligned} \quad \text{Equation 7}$$

Then (discounting trade costs), it will be profitable for A to outsource to B the part of its production corresponding to $y(\mathbf{k}')$.

Thus, a steep addition to bilateral trade costs reduces not only the competitiveness of the targeted country, but will also negatively affect the protected industry and raises, in relative term, the productivity of its foreign competitors. The net effect for the A country industry that was supposed to be protected by the high trade barriers may be negative if it faces competition from third countries on its home and export markets.

It is therefore particularly relevant, at the moment of analysing the effects of raising the bilateral trade barriers in a GVC context, to look at (i) the shares of bilateral trade in intermediary goods vs. final ones, and (ii) the relevance of exports for the home industry. Bosker and Westbrook (2018) provide a formal treatment of this ambivalent result on vertically specialised firms in the more general case of a multilateral reduction of trade costs. They show that the exposure differs when firms are further up- or downstream in the global production network. The aim of the extraction-cum-substitution method is to map more precisely these side effects.

⁷ For a proof, see Shiozawa and Fujimoto (2018) Theorems 6.1 and 6.2.

2. Hypothetical Extraction and Substitution and Trade in Value-Added

The empirical method builds on two interrelated strands of research, both of them based on input-output models. The first one is the “Extraction Method”, which has been used in national and regional input-output analysis to identify the most relevant sectors or regions. Miller and Lahr (2001) provide a review of the different approaches under this method; Dietzenbacher and Lahr (2013) generalize the approach. We will return to this approach after presenting the main tenets of the analysis of trade in value-added.

- Measuring trade in value-added

This strand of empirical research is directly associated to the analysis of trade along Global Value Chains (GVCs), also known as “Trade in Value-Added”. It is closely associated with new dimensions in trade statistics, following the concept of Vertical Specialization. Balassa (1967) defined Vertical Specialization as the production process of a commodity when it is divided into a vertical trade chain, each country adding value at each stage of the production process. Hummels, Ishii and Yi (2001) extend Balassa’s concept and propose a measurement method based on national input-output tables. In their seminal contribution, they split gross exports between a share of domestically produced inputs and a share of imported ones. Daudin, Rifflart and Schweisguth (2009) apply this new line of trade analysis to international input-output models.

The first application using official data was published in 2011 by WTO and IDE-JETRO, with an application on Eastern Asia. It is also the guiding methodology used by the Trade in Value-Added (TiVA) database (OECD-WTO, 2012). Jones, Demirkaya and Bethmann (2019) provide a comprehensive review of the applications of this concept to trade analysis in the business and economics literature.

The value-added decomposition of trade starts with the so-called Leontief model:

$$\mathbf{X} = \mathbf{A} \cdot \mathbf{X} + \mathbf{Y} \quad \text{Equation 8}$$

where:

- X**: is an $n.k*1$ vector of the output of k industries within an economy of n countries.
- A**: is the technical coefficient $n.k*n.k$ matrix describing the interrelationships between industries; with a_{ij} the ratio of inputs from domestic industry i used in the output of industry j .⁸
- Y**: is an $n.k*1$ vector of final demand for domestically produced goods and services, including exports.

The contribution of exports to the country’s GDP is equal to:

$$\mathbf{v} \cdot (\mathbf{I} - \mathbf{A})^{-1} \cdot \mathbf{e} \quad \text{Equation 9}$$

where:

- v**: is a $1 \times n.k$ vector components m_j (ratio of value-added to output in industry j)
- I**: is an $n.k \times n.k$ identity matrix.
- e**: is a $n.k \times 1$ vector of gross exports by industry.

⁸ Matrix and vectors will appear in bold character in the paper.

This “Leontief decomposition” approach has been further refined by Koopman, Powers, Wang and Wei (2011) who decompose GVC trade into several trade in value-added indicators. Pursuing this line of work, Wang, Wei and Zhu (2013) (WWZ from now) extend the information contained in inter-country input-output tables to decompose GVC trade and derive additional indicators.⁹

The domestic value-added or GDP in each country/sector pair is generated from the following three types of production activities:

- (1) Production of domestically produced and consumed value-added
- (2) Production of value-added embodied in final product exports
- (3) Production of value-added embodied in exports of intermediate goods and services. WWZ further splits this value-added into three additional categories: (a) Directly absorbed by partner country r without further border crossing; (b) Returned (re-imported) to exporting country s and finally consumed domestically; and (c) Indirectly absorbed by partner country r or re-exported to a third country t .

We use both the Leontief and the WWZ decomposition implemented in Quast and Kummritz (2015) for mapping the pre-crisis trade in value-added, then use extractions and simulations for building successive scenarios.

- Extractions and simulations

A recent paper by Los and Timmer (2018) shows that these new “Trade in VA” measures can be also derived with the method of hypothetical extraction in a general input-output model. Their starting point is the inter-country input-output model presented in Figure 3. In the traditional hypothetical extraction method, one deletes the industry that is analysed in the actual input-output matrix (Dietzenbacher and Lahr, 2013). This is simply done by setting to 0 its row or column in the input-output matrix and in the final demand vector. A new Leontief model is constructed. The difference between the initial and the modified models indicates the importance of the industry for the entire economy (a country in traditional input-output analysis, or the world economy in the present case).

In their application to the measure of trade in value-added applied to an intercountry model, Los and Timmer (2018) do not extract entire industries from the system, but only some transactions. So, only part of the line or column is set to 0, indicating trade to or from a specific set of industries belonging to a specified country.

For example, imagine we want to know the importance of Chinese value chains exporting to the USA. If China is country 1 in Figure 3 and the USA is country 2, Los and Timmer (2018) suggest to set to 0 all the elements in \mathbf{A} corresponding to Z_m^{12} as well as the output of industry “m” imported by country “2” for its final demand (\mathbf{Y}_m^{12}).

A new GDP for country 1 is calculated:

$$GDP_1^{*2} = \mathbf{v}_1^{*2} \cdot (\mathbf{I} - \mathbf{A}_1^{*2})^{-1} \cdot \mathbf{Y}_1^{2*} \cdot \mathbf{i} \quad \text{Equation 10}$$

⁹ The calculus behind the WWZ decomposition is too complex to be exposed here and we refer the interested reader to the original papers.

Where:

\mathbf{v}_1^* is the $n.k$ vector as in Equation 9 with all elements not corresponding to the extracted country set to 0;

A_1^{*2} and Y_1^{*2} are the matrices of technical coefficients and final demand after extraction of exports of product “m” from country “1” to country “2”;

\mathbf{i} : is the summation vector of dimension $n.m$ (all elements are equal to 1)

The difference between the actual GDP_1 value of “1” and GDP_1^{*2} gives the value-added created by “1” and consumed by “2” for industry “m”.

$$VAXD_{1,2}^m = GDP_1 - GDP_1^{*2} \quad \text{Equation 11}$$

VAXD is also known in Trade in Value-Added analysis as the indicator of the value-added embodied into exports. It is one of the indicators calculated by Wang, Wei and Zhu (2013) but using another decomposition method.

In commenting their approach, Los and Timmer (2018) state page 10 something that is of utmost importance for the present paper: “*We would like to emphasize that GDP_r^{*s} should not be seen as the GDP level that would result if exports to s would be prohibitive. In a general setting with more flexible production and demand functions, substitution effects will occur. As a consequence, the total production structure and final demand levels will change and the global production structure after the shock will not be represented by A_s^* and Y_s^{*s} . $VAXD_{rs}$ should therefore be regarded as an upper limit of the loss in GDP_r^* and is most meaningful if compared to other scenarios of extracted transactions*”.

Our approach builds on their suggestions: not only do we extract some transactions (those affected by the bilateral trade conflict), but we also contemplate for the replacement of extracted outputs.¹⁰ In our simulations, we will let other industries seize the business opportunity created by the withdrawal of a competitor and fill the gap opened by the exit firms. The extracted inputs will be replaced by a mix of domestic and imported inputs. The substitutive trade flows will follow a standard gravity equation reflecting the parameters of the pre-crisis situation, in particular that trade frictions with other trade partners are unaffected by the bilateral trade conflict.¹¹

As in Los and Timmer (2018) example and using the notation in Figure 3, extraction means we first set to 0 all the elements in \mathbf{A} corresponding to Z_m^{12} as well as the output of industry “m” produced by 1 and imported by country “2” for its final demand (Y_m^{12}) in **Error! Reference source not found..** In the case of final demand (the same reasoning applies to intermediate products), the bilateral flows of products “m” exported by country “i” to country “j” respect the following gravity equation:

$$Y_m^{ij} = \frac{X_m^i X_m^j}{X_m d_{ij}^2} \quad \text{Equation 12}$$

¹⁰ This suppose a deviation from the traditional Leontief production functions, which do not contemplate substitution and suppose that inputs (intermediate and primary) are complementary. A radical interpretation of this strict complementation means that an extraction is disruptive. Computable general equilibrium models, at the contrary, do contemplate substitution effects.

¹¹ This hypothesis assumes that bilateral distances are mutually independent, a traditional assumption in gravity modelling that has been challenged by Anderson and Wincoop (2003).

where Y_m^{ij} are exports of m from i to j , X_m^i is i 's economic size from the supply-side perspective (the mass of products supplied at origin i), X_m^j is j 's market size (the mass of products m demanded at destination j). At world level, total supply of m equals total demand and is noted X_m ; d_{ij} is the economic distance between i and j (a measure of the bilateral trade frictions that impede pure free trade).

What happens when an industry producing m in country s is excluded from exporting to country r ? The relative sizes of all other producers for this specific market are artificially increased because s has to withdraw from the competition. From the specific viewpoint of the competition on the r market, it is "as if" X_m^s had been extracted from the World competition X_m . The new gravity equation for this specific market is:

$$Y_m^{ir} = \frac{X_m^i X_m^r}{X_m' d_{ij}^2} \quad \text{Equation 13}$$

For all $i \neq s$; with $X_m' = (X_m - X_m^s)$.

And $Y_m^{sr} = 0$ due to extraction.

Keeping r final demand X_m^r and d_{ij} constant by hypothesis, the ratio between the new sales from country $i \neq s$ to country r and the previous ones is, after a few substitutions:

$$\frac{Y_m^{ir}}{Y_m^i} = X_m / X_m' \quad \text{Equation 14}$$

After extraction and substitution, (i) the exports of s to r drop to 0; (ii) the sales of all other countries - including r itself - already present on the r market increase and (iii) the ratio of the new market shares between these countries remains similar to their pre-extraction ratio (See Annex for further discussion).

At the difference of Computable General Equilibrium models (CGE), the substitution does not result from a complex optimization process; the additional sales are reassigned in proportion of the existing market shares before the extraction. Actually, the simulation is more akin to analysing a shock to the general equilibrium described by input-output data from a partial equilibrium point of view.¹²

While the philosophy of the KISS exercise is to avoid changes in prices, to keep demand in line with the equilibrium situation as long as possible, we make a short-term exception. Substituting inputs at short notice may imply a higher price for procuring the additional products, since shifting to new suppliers may be costly. The rise in prices for the additional supplies produced in addition to the previous requirement is probably not permanent. When the supply chain leaders renegotiate their long-term procurement contracts with their suppliers, they will ask for the same price for all the inputs supplied. Thus, after some time, input prices should return to their initial situation. The short-term

¹² From an economic perspective, the ex-ante situation was the product of a general equilibrium and the existing market share represented the relative competitive advantages of the various countries on the extracted market. Reassigning the market shares in proportion of the previous equilibrium means simply the relative competitiveness of the non-extracted industries and the impact of trade frictions as specified in a standard gravity model have remained the same, under a *ceteris paribus* assumption.

case is illustrative of the negative feed-back on the industries that were supposed to be protected by the high trade barriers: the increase in procurement cost reduces their competitiveness and may induce a severe blow on the profitability of the most exposed ones.¹³

This is not the end of the story. The firms affected by the extraction of some of their markets will try to redeploy its production to other markets. This “export restructuring” in the face of trade conflict is known as “deflection” in the trade literature. In order to exclude a situation of dumping that would affect final prices (and demand, which is supposed to remain constant in this phase), we will consider that extracted industries will redeploy the lost output to other markets by marketing more aggressively their products. The previous suppliers will be displaced in proportion of their previous market shares, but prices will not be affected.

It may not be possible for the extracted industry to redeploy all the lost sales to other markets, because its competitors will defend their market share. Thus, redeployment will probably apply to a smaller share of the lost sales. In absence of any additional information on the degree of substitutability of the respective product, we will consider three scenarios. Two of them are extreme solutions: zero or full substitution. The third is a mixed one where only half of the lost production can be redeployed to other markets. This simple solution is also, from a statistical perspective, the “expected value” of the redeployed share when no prior information is available, as long as the probability distribution of the possible outcomes is symmetric. If, in addition, the distribution is unimodal (a traditional hypothesis in statistics), then the expected value is also the most probable.

These scenarios translate into the following simulation sequence when considering that the trade war between country “A” and “B” is initiated by “A” and affect some industrial product “q”:

1. The first stage extracts B’ exports of the targeted industry to A for intermediate and final goods. This step is similar to traditional extraction without replacement.
2. In a second stage, other countries substitute exports of “B” to “A” for both Intermediate and Final Goods but the additional sales of intermediate goods take place at a higher price (the price of final goods remains the same in order to keep Final Demand constant through all the scenarios). The corresponding technical coefficients for the industries in country “A” that have to substitute for the inputs originating from “B” are now larger and the rate of value-added is smaller.¹⁴
3. With the passing of time, the higher procurement cost disappears and the competitors of “B” supply their intermediate products to “A” at the pre-crisis prices. The rate of value-added of the industries in “A” returns to its pre-crisis situation.
4. Country “B” aggressively markets its product to third countries in order to compensate for the market losses in “A”, without changing the price of its intermediate and final products. There is no change in the volume and structure of final demand. This scenario has two variants:

¹³ Perhaps forcing them to exit if the loss in price competitiveness is irreversible. The present method cannot properly model the price effects on market shares. It is one of its limitations compared to CGE modelling.

¹⁴ By construction, the price of the products “m” sold to final consumers do not change: Value Added in the industries “2” need to be reduced in proportion of the higher procurement cost, in order to keep the price of the output unchanged. Here again, we remain in a partial equilibrium approach where only inter-industry trade is affected, other things remaining constant.

- a. Partial substitution: only 50% of the losses can be redeployed. This variant corresponds to the expected value, from a statistical perspective.
- b. Full substitution: all sales are redeployed, if feasible.¹⁵

Except for the short-run scenario, the simulation does not change the prices nor the rate of value-added. The substitution does affect the geographical origin of purchases for both intermediate and final products and the monetary value of sectoral trade and value added will be affected in relation to the variations in sales and output. So will be GDP and employment. We mentioned when commenting Table 8 above that the total value of final demand remained constant by construction and only its distribution was affected by the process of extraction-cum-substitution and redeployment. This is obviously an over-simplification as income, measured through the GDP, does not remain constant. But keeping final demand constant has the merit from an exploratory mapping perspective of isolating the trade effects from other considerations. And this mapping was the main objective of our simulation exercise.

Yet, let's go one step further and look at final demand.

5. Final Demand adjusts to changes in GDP. In this final step, a new vector of Final Demand is calculated applying an income elasticity of 1. In other words, a country's Final Demand varies in direct proportion of the change in its GDP and the model is re-estimated. Here again, we take the simplifying hypothesis of a constant unitary income-elasticity of demand for all categories of goods and services. This KISS option corresponds also to the absence of prior information in a Bayesian inference perspective. It is obviously an over-simplification as we know that the income-elasticity of demand varies according to products but also to per capita income levels (the so-called Engel's Law).

The procedure stops here, even if this is only the first stage of an iterative process: in truth, each change in the final demand Y does induce a new change in output X via the Leontief model in Equation 8, which in turn modifies GDP and final demand, and so on and so forth until a convergence is reached. To keep with our favoured KISS approach, we do not model this convergence and stop at estimating the first step, using the expected scenario corresponding to the mean value of substitution.

The extraction-cum-substitution method is exploratory in nature, it is both its strength and its limitation. At the difference of CGE modelling, it does not pretend to "predict" an outcome of a bilateral trade conflict on the World Trade Network. As mentioned in footnote 13, our substitutions cannot properly reflect the effects of prices on demand. But this extraction-cum-substitution approach offers a series of "markers" corresponding to extreme or expected points that should help mapping the inter-industrial effects of what remain largely uncharted waters: the direct and indirect effects of a bilateral trade war between two economic giants. The straightforward nature of the methodology allows to progress step by step in the implementation of the model, disaggregating clearly the various

¹⁵ If the extracted industry is dominant on a given market and its competitors have little market share, it may not be possible to fulfil the redeployment target, even after taking 100% of the competitors' market share. It should be noted that, because the Leontief matrix is the limit of the polynomial function $(\mathbf{I} + \mathbf{A} + \mathbf{A}^2 + \mathbf{A}^3 + \dots + \mathbf{A}^n; n \rightarrow \infty)$, the simulation may not be a linear function and the 100% and 50% variant may lead to a range of GDP outcomes, depending on the weight of the quadratic and higher level coefficients of the suite. In practice, nevertheless, the elements of the extra-diagonal bloc $\tilde{\mathbf{A}}$ of \mathbf{A} , corresponding to imported inputs are much smaller than one, and the simulation could be simplified (we do not use this short-cut in the R program in Annex).

individual effects. For this particularity, and compared to more holistic general models, the method is better used as an exploratory device that helps understanding the various dimensions of a complex inter-industrial reality. As we shall see, it opens also the door to further statistical analysis of the countries' mode of insertion in the World economy.

3. Model and simulation results

In order to test the methodology and visualize more clearly the cascading effects of a bilateral trade war on other trade partners, we use a toy model example, based on a very simplified representation of the World economy.

1. Model starting point

The guiding principles for the designing the Toy Model were as followed: The model must be as simple as possible, yet show the direct and induced impacts of a bilateral trade disruption between two large and inter-connected countries such as China and the USA. The specificities of each country, represented schematically by the structure of their production and trade, should be as schematic –or exaggerated-- as possible, in order to identify clearly the different impacts according to each country's specialization in the global value chain.

The Toy economy includes six countries, each economy has three sectors, producing commodities (agriculture, mining, fuels), manufactures and services. Services are not tradable as final products. Sectors are identified by letters P, M, S. Each country has specific economic characteristics and comparative advantages:

Sierra is a small, services-oriented economy. Sierra is the sole economy in the model that exports services as intermediate products. In the model, Sierra would stand for a small developed or emerging economy relying on financial and business services exports.

Papa is mainly exporting commodities, with a reduced manufacturing sector for domestic consumption. In the Toy Model, Papa personifies natural resources-rich developing economies.

Kilo and **Echo** are high technology manufacturers. In addition, Echo is a large market for consumption. Here, one may identify Kilo with Japan and Echo with the USA.

Charly and **Mike**: Two low and middle technology manufacturers, using their own inputs and processing imported inputs for exports. Mike exports also commodities to Charly as intermediate inputs, but does not import intermediates from Charly. Mike's manufacture supply chain is focused on Echo, Charly's GVCs are more diversified. In a very simple way, we can consider that Charly –a large emerging country-- stands for China and Mike –a medium sized emerging country with a sizeable oil sector—stands for Mexico.

Trade conflict is between Charlie and Echo, and affects trade in Manufacture (both intermediate goods such as parts and components, and final goods such as consumer goods, machinery and equipment). Echo initiates the conflict and block all bilateral trade in manufacture from Charlie. The effects of trade restrictions on input-output, production and income are measured through extraction method.

The building block for the simulation is the Toy Model input-output matrix, including inter-industry trade, final demand, production and value-added. This matrix is also called the table of direct requirements.

Table 1 Toy Model: Initial Inter-industry trade, sectoral production and Value-Added in monetary terms

Source: Author's elaboration based on a purely hypothetical case for illustration purpose

In the Toy Model, services are only exported as intermediate by Sierra and primary goods (agriculture, mining, fuels) are exported by Papa and Mike. Manufactures are exported by all other countries. Table 2 shows the matrix of final demand (consumption and investment products) before the trade war. Echo imports more than 50% of its final consumption of Manufacture, especially from Charlie and Mike. Note that in this presentation, imports of final products are on the extra-diagonal elements.

At macro-level, the industrial interactions are measured by the Leontief matrix, net of the final output $[(\mathbf{I}-\mathbf{A})^{-1} - \mathbf{I}]$ which gives the total requirements needed to produce one unit of industrial output when all direct and indirect interactions have taken place. The input-output matrix in Table 1 provided a view of the direct requirements to produce one unit of output for each sector of activity. To understand the difference between direct and total requirements, let's take an example. In order to produce one unit of manufacture, Papa's industry purchased 0.25 from Papa commodity. Charlie's industries were more efficient in the use of commodities and

required only half this amount (0.12). But this is not the end of the process, because Papa's primary sector had to purchase additional inputs in order to produce the additional products required by its manufacturing clients. For one additional unit of commodity produced, Papa primary sector needs to purchase 0.07 manufacturing inputs from its own industry and from Echo and Kilo manufacture. In order to produce this additional 0.07, these manufacture sector will need to purchase additional inputs from other industries, domestic or foreign). And so on and so forth. The sum of all these additional requirements can be calculated using the Leontief model, to obtain the table of total requirements (Table 3). It is obtained multiplying each column of the Leontief matrix net of final output by the output of the corresponding industry.

There are two main important differences between direct and indirect requirements (Table 1 and Table 3, respectively). First, the total requirements are much larger than the direct ones. While Charlie_M firms purchased 240 million of inputs to produce 485 of output, the total requirement induced by this production amounts to 438 million, 83% more than directly required by Charlie_M industry. The ratio Total Requirements/Direct Requirements varies from 1.75 to 1.85 when considering all industries in our simple model. This is linked to the multiplier effect of the Leontief model: as long as there is a sufficient productive capacity, each unit of additional demand will generate a higher level of total production in all the industries that are involved directly or indirectly with the production process.

The second implication is more directly related to the economics of trade in value-added. When we look at total requirements, we see that some products that are non-tradable and are not directly internationally exchanged, such as the services in our Toy Model, become part of total requirements. For example, Charlie_M manufacture production indirectly induces some 7 million of additional services activity in Papa and Kilo, 6 in Mike and 4 in Echo; yet these countries did not directly export any services at all. Because of the existence of these intangible international trade flows, the analysis of the macro effects is much richer and also more complex than what was perceived at micro level.

Applying the Leontief decomposition of GVC trade is closely related to the table of total requirements, but instead of indicating the gross value of production, it indicates the origin of the value-added. Applied to exports, it shows the contribution of all trade partners in the value of the

products exported by a given industry. Table 4 shows the results obtained for Charlie’s gross exports of manufacture, totalling 255 million (55 of intermediate goods and 200 of final products).

Table 4 Global Value Chain Decomposition: Value Added embodied in Charlie’s Manufacturing Exports, by country/sector of origin

Source: Elaborated using R package Decompr (Quast and Kummritz, 2015)

10% of the exported value originates from Papa’s primary sector value-added. In second position of the foreign contributors, Echo’s manufacture contribution is close to 6%. We see that Mike’s contribution is also at 5% for its commodity sector, but the contribution of its manufacture sector is above 1.5% despite not exporting anything to Charlie: its contribution is indirect, through the exports of parts and components to Echo’s manufacturing sector, which in turn exports to Charlie. One can check that the sum of the contribution is 100%: the total exported value is fully split between the various countries and sectors that contributed in the value chain.

Wang, Wei and Zhu (2013) further decompose the value added into several sub-components. Table 5 presents the WWZ decomposition by importing countries, showing the source industry and the use country (when the exporting and importing sectors are the same, the value is 0). Note that the value added is the domestic aggregate and not only the value created by the exporting industry itself. In the present case, Charlie’s manufacture exports also domestic value-added from the primary and the services sectors

WWZ decomposition is rather complex (see Figure 4) and it is not the place here to go much into details, and we refer the readers to Wang, Wei and Zhu (2013) and Quast and Kummritz (2015). For example, DVA_FIN represents the domestic VA embodied in exports of final product. Those products are consumed in the importing country and do not continue participating in a value chain. DVA_INT is the VA embodied in intermediate goods that will be further processed as final goods and absorbed by the importer. DVA_INTrex correspond to the exported domestic value-added that is reprocessed by the importing country and re-exported to third countries as intermediate goods. DVA_INTrex is further split into three categories according to its use by the second importer.

Figure 4 WWZ Decomposition of Domestic Value-Added embodied in Gross Exports

Source: to Wang, Wei and Zhu (2013)

RDV concerns the domestic value added that returns to the exporter, embodied in imports of final or in intermediate goods. Other terms, not included in

Figure 4 which deals only with the domestic value-added content of gross exports, correspond to other concepts: MVA is the foreign value-added embodied in the exports and sourced from the importing country, OVA is the foreign value-added embodied sourced from all other countries. MVA and OVA are further split according to their use for intermediate or final goods. DDC, ODC and MDC capture double counting, a statistical issue happening when trade takes place within GVCs. Because pure double counting of foreign value-added in a country's exports can only occur when there is back and forth trade of intermediate goods, it is also an indirect indicator of the deepening of GVC trade (Wang, Wei and Zhu, 2013).

Source: Elaborated using R package Decompr (Quast and Kummritz, 2015)

The WWZ decomposition will be useful to interpret the results of the simulations, as it provides interesting information on the GVC specialization of each country. For example, Charlie's

manufacture is more downstream than Kilo's, if one looks at the use of the respective products: Most of Charlie's exports of manufacture to Kilo are used to satisfy its domestic final demand (DVA_FIN), while Charlie uses Kilo manufacture more as intermediate inputs, either for domestic consumption (DVA_INT) or for re-exports (DVA-INTrex).

2. First and second rounds of the trade conflict

The trade war between Charly and Echo affects manufacture goods and is initiated by Echo. Charlies' manufacturing exports to Echo are prohibited (extracted) for both intermediate and final goods. This first stage of the trade conflict can be split into two rounds, if we look at the short run and long run effects.

- Short term: Other countries, including Echo's manufacture itself, will substitute Charlies exports to Echo for both Intermediate and Final Goods at the same price. But in the short run effects, some of Charlie s' intermediates goods are not easily substitutable and will have to be procured by Echo at a higher cost (30% premium in this simulation). This situation arises because, for example, Non-Charlie suppliers of this type of products will seize the opportunity to increase their mark-up margin, or will have to increase production above their normal capacity, paying additional production cost. This impact to Echo is limited to intermediate goods only, and there is no change in the price of Final Demand products. In this simulation, the additional inputs sourced from domestic and foreign suppliers required by Echo are 30% more expensive than the purchases established through previous arrangements. Other suppliers to Echo will benefit from the higher price of the additional production required to substitute Charlies exports of intermediate goods to Echo. Echo' s products will be more expensive or its industry will have to reduce its mark-up to remain competitive. If this short-term effect extends to the medium-term, Echo's industry may well have to exit because they are short of competitively priced intermediate inputs (a situation which was depicted in Figure 2, above).¹⁶
- Long term: With the passing of time, supply adjusts to demand and the additional mark-up and production costs disappear. The substitution of Charlie's sales of intermediate products is done at pre-crisis prices.

Table 6 shows the impact on direct and indirect exports of manufacture value-added to Echo, before and after it blocked manufacture imports from Charlie. In the first round, Charlie's exports of manufacture VA to Echo falls by 94%.

Note that if direct exports were blocked ('extracted'), Charlie's manufacture Value-Added would still be indirectly purchased by Echo when it is embodied into third countries intermediate and final products. Echo's sales on its own market increase a lot (by 33.4 million, an increase of 24%), but the major relative gains are registered by Mike's manufacturing sector, which jump almost 30% in the short term, due to the combined effect of an increase in demand (both final and intermediate) and in

¹⁶ In truth, the simulation does not look at the market losses that would be caused by this loss of price competitiveness and our model assumes that Echo's firms adjust their mark-up to keep their output price competitive. In order to include this price effect, the model would need to take into consideration input price elasticities. Doing so would add complexity to a model we wished to keep as simple as possible. Such price effects would be better treated in a general equilibrium context.

the price of intermediates.¹⁷ When prices return to their long-term value, the relative gains of all Echo's trade partners are slightly reduced, except for Echo's manufacture, which benefits from the price reduction on the substituted inputs to recuperate its initial rate of value-added.

Table 6: First round of the trade war: demand of manufacture value-added by the protected market by origin

	In monetary value			Index Initial=100	
	<i>Initial</i>	<i>Short</i>	<i>Long</i>	<i>Short</i>	<i>Long</i>
Sierra_M	2.8	2.8	2.8	100.8	100.4
Papa_M	3.0	3.0	2.9	98.7	97.5
Kilo_M	40.4	42.4	41.4	105.0	102.5
Charlie_M	50.0	3.0	3.0	6.0	5.9
Mike_M	58.0	75.1	74.0	129.5	127.6
Echo_M	138.5	171.9	172.2	124.1	124.4

Note: changes are expressed in percentage of initial pre-crisis situation before the trade war. Additional intermediate inputs needed to substitute Charlie's one in Echo are 30% more expensive.

Table 7 provides information on the overall effect of the sectoral impacts presented above. As expected in this first round, Charlie's economy is the most affected, as it suffers a 20% drop in its GDP from the loss of its most important export market. Echo's sectoral GDP increases by 12%, but Mike (the middle-income country specializing highly integrated into Echo's manufacturing sector) gains more in relative terms in the short term (13%) because it increases its Echo market share while benefiting also from the increase in procurement prices. These price benefits are eroded in the long term, and its long-term gains, while remaining significant, return to being slightly lower than Echo's.

Table 7: First round of the trade war: sectoral value-added of the manufacturing sector

	In monetary value			Index Initial=100		
	<i>Initial</i>	<i>Short</i>	<i>Long</i>	<i>Initial</i>	<i>Short</i>	<i>Long</i>
Sierra_M	25.0	25.0	25.0	100.0	100.1	100.0
Papa_M	45.0	45.0	44.9	100.0	99.9	99.8
Kilo_M	295.0	298.0	296.6	100.0	101.0	100.5
Charlie_M	245.0	194.9	194.8	100.0	79.5	79.5
Mike_M	145.0	163.7	162.2	100.0	112.9	111.9
Echo_M	285.0	319.0	320.3	100.0	111.9	112.4

Note: see Table 6

The manufacturing sector of other countries do not gain much, because their gain on the Echo's market are compensated by lower sales of intermediate products to Charlie. The lower sales may come from two effects: the first one is the cumulated effect of direct and indirect demand originating from the reduced activity of Charlie manufacture, the other one is the re-composition of the total requirement table due to the changes in Echo's direct coefficients. We look more in detail into these systemic effects in the next section.

¹⁷ In truth, Charlie's indirect sales should not have indirectly benefited from the increase in the price of substituted inputs. But the impact is very small and disappears in the long term.

3. Third round: Trade redeployment and struggle for market shares

Charlie's manufacturing sector should not be expected to remain passive after the loss of its Echo market. Because Echo was such an important market, Charlie's factories are now running at a portion of their initial capacity and part of the labour force remains idle. We can therefore expect Charlie's manufacture to redouble efforts to sell more intermediate and final products and increase their global market share outside Echo.

Excluding, as in the rest of the model, any change in unit price, Charlie uses only marketing efforts (promoting products and brand recognition). This effort is directed at both its exports and its own domestic market. In the process, they displace other suppliers, including Echo's exports (excluding, obviously, Echo's market which remains closed to Charlie's products). Because gaining market share is not an easy process in the face of stiff competition, Charlie cannot expect to recoup all its losses, and our preferred scenario on a purely statistical criterium is the one where only half the losses can be recouped.

But for illustrative purpose, Table 9 and Table 8 show the changes occurring when full redeployment takes place. This scenario has additional properties. It is only in case of full redeployment that the total value of final and intermediate demand remains constant: the losses of some parties in some markets are fully compensated by gains somewhere else. This extreme case has also the merit of attributing changes exclusively on variation in trade, and not on variations of total demand (this option is modelled in the final steps). Note also that in full or partial substitution, the rate of value added remains constant for all industries, including Echo's (last row of Table 9) once the input prices have returned to their long-term trend.

The evolution of final demand sheds important light on what will be the overall economic impact of the trade war. By construction, total demand does not change at country level, only the distribution of this demand between providers, be they domestic and foreign sources. Because Charlie is barred from exporting to Echo, it has to redeploy its exports to all remaining markets. In the case of full redeployment, Charlie's competitors will suffer net losses ranging from -6% to -11%, with the exception of Echo and Mike. Echo is protected from Charlie's increased competition on its own domestic market and registers a 10% net increase of its sales of final products. Mike manufacture industry, which exports mainly to Echo, remains a net winner with gains balancing losses by a positive margin of 4%.

Echo's gains remain positive because Charlie has not retaliated by blocking its imports of Echo's products and Echo's industry does not rely much on exports. Yet, we could have expected Echo's market shares to have suffered during the "Short Run" simulation, due to the losses of price competitiveness following the disruption of its supply chain connections with Charlie. These losses are not calculated in the model, as mentioned in footnote 16. It is implicitly assumed in the model that the disruption is manageable and that Echo's manufacture firms absorb the higher production costs by reducing their mark-up margin. This assumption is probably optimistic.

In a Tit-for-Tat situation, the same simulation procedure would have to be repeated, with the difference that it would be Charlie blocking Echo's exports of intermediate and final manufacturing

goods. The modelling process would remain exactly the same and the positive and negative spill-over effects on by-standers even larger.¹⁸

Note: Changes are expressed in percentage of initial pre-crisis situation, before the trade war. They affect all sectors using Charlie's manufacture as inputs, even if only manufacture is shown here.

Changes in direct requirements (Table 9 above) are compounded when looking at indirect requirements (Table 10). They affect all productive sectors using Charlie's manufacture as inputs or not, at the difference of direct requirements where only the markets where Charlie was active in the initial situation were affected. Another difference with direct requirements, which sum up to the same total in order to maintain constant the rate of value-added, the sum of total requirements changes from

¹⁸ With an important qualitative difference from an analytical perspective. We mentioned that the initial simulation could be understood as a partial deviation from a general equilibrium state described by the actual input-output table. It is no more the case as the retaliation will be modelled on the basis of the outcome of the first iterations, which differs from the initial equilibrium.

industry to industry because each one has different production function (as measured by the technical coefficients). Note also that while Echo had stopped all direct imports of Charlie's inputs, its indirect demand drops only by 66%, instead of 100% as observed in Table 9). This reflects Charlie's value-added content embodied in inputs imported by Echo from third countries which processed and re-exported Charlie's intermediate products (this corresponds to the DVA_INTrex in Table 5).

For many countries, the variation is similar across industries. This is due to the sparse nature of the initial direct coefficients, where countries export only one intermediate good (Primary, Manufacture or Services). This intermediate good, in turn, is composed of various components supplied domestically from the two other industries or imported from other countries. Therefore, while the changes in direct requirements showed only a single change (e.g., 25% increase in purchases from Charlie_M), the increase will be reflected in a change of total requirements corresponding to all sectors contributing to the production of Charlie_M.

Note: Changes are expressed in percentage of initial pre-crisis situation, before the trade war. They affect all sectors, even if only manufacture is shown here.

The combined changes in total requirements and in the distribution of final demand have an impact on GDP. Table 11 shows the evolution of the sectoral value-added through the various steps of the simulation, from the initial pre-crisis situation to extraction and substitution (short term implying a 30% increase in the additional procurement costs substituting Charlies extracted inputs) then redeployment by Charlie of the extracted sales. Figure 5 shows the evolution of the total GDP index, based on the initial situation.

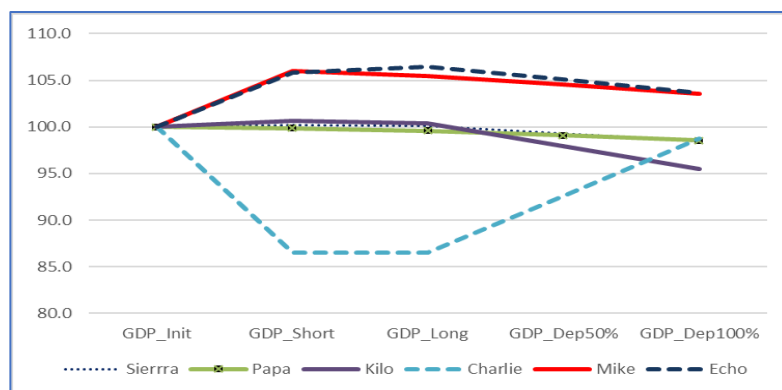

As mentioned, the 50% redeployment case is the expected one from a statistical perspective while the 100% case is an extreme point that has the advantage of keeping constant total demand. Echo is gaining in all scenarios, albeit its gains are eroded if Charlie partially displaces it from its export markets (from a gain of 12% to 10% in manufacture, and from 6% to 4% for GDP). Charlie recoups almost all its substantial losses in case of full redeployment: its manufacture sector, which retracted by 20% after losing the Echo market, ends with a loss lower than 5%. The impact on its GDP follows a similar pattern: from -13% to only -1%. This is built in the simulation scenario, which allows

Charlie to redirect its extracted sales to other markets, be they domestic or export. The more plausible 50% redeployment scenario indicate that Charlie would suffer a -7% recession in GDP, induced by a 17% drop in its manufacture value-added.

Table 11 Evolution of sectoral value-added through the different simulation scenarios

Figure 5 Evolution of GDP through the different simulation scenarios (Initial=100)

The contrast between no redeployment (the Long-term extraction-cum-substitution scenario) and full redeployment indicates that the main casualties in a bilateral trade war between two large traders are the by-standers if the targeted industry is able to redirect its exports to other markets. In the present case, Kilo is the country most affected by export re-structuring. Its manufacture industry gains very little if no redeployment takes place (0.5%) but loses more than 8% if Charlie is able to redeploy all its lost sales to other markets. Even in the most plausible case of 50% redeployment, Kilo GDP still registers a 2% recession. Mike, which is not exposed to Charlie's competition (its main export market for manufacture is Echo, a market that exclude Charlie's products) gains about 4% in total (almost 10% for manufacture only). Its gains are even larger if Charlie can only redeploy 50% of its lost sales, especially for its manufacture sector (9%) while its primary sector, which exports commodities to Charlie and lost 5% after Charlie's extraction, would recoup all its losses and even register small gains if Charlie's recovery is maximum.

4. Fourth round: Final demand responds to changes in gross domestic income

We mentioned when commenting Table 8 above that the total value of final demand remained constant by construction and only its distribution was affected by the process of extraction-cum-substitution and redeployment. This is obviously an over-simplification as income, measured through the GDP, does not remain constant.

Let's go one step further and see what will happen to our Toy Economy if the demand emanating from each country adjusts in proportion of the changes in its GDP.

Table 12 Final Demand Adjustments: changes with the no-adjustment situation (percent)

Sector	50% redeployment	100% redeployment
Sierra_P	0.0	-0.5
Sierra_M	-0.2	-0.3
Sierra_S	0.6	0.1
Papa_P	-0.6	-0.3
Papa_M	-0.8	-0.6
Papa_S	-0.9	-1.2
Kilo_P	-2.0	-4.1
Kilo_M	-1.5	-2.0
Kilo_S	-1.9	-4.0
Charlie_P	-7.3	-1.4
Charlie_M	-6.8	-2.7
Charlie_S	-7.3	-1.4
Mike_P	0.9	1.4
Mike_M	4.1	3.3
Mike_S	4.1	3.3
Echo_P	4.9	3.6
Echo_M	3.6	3.0
Echo_S	4.9	3.6

Note: changes are expressed in percentage of the corresponding (50%-100%) simulation as in Table 11.

As expected, the adjustment favours the winners and penalises the losers, due to the strong home bias of demand (most of demand is covered by local production). Another influential factor is the difference in trade exposure: countries exporting to winning countries will gain relatively more than countries exporting to countries registering a recession due to the trade war.

Echo's gains are amplified, as well as Mike's. If Charlie is not able to redeploy 100% of its lost exports to Echo, it is doubly penalised: first, because its Final Demand will shrink as its GDP did; second because it is not able to benefit from Echo's bonanza, being barred from exporting to this market. Even if it can redeploy 100%, the second penalisation will still apply, while its direct competitors will be able to recoup some of their losses due lower domestic demand and to Charlie's increased competition by selling more to Echo.

As mentioned in the methodological section, the KISS procedure stops here even if this is only the first step of an iterative process where each change in GDP induces a new change in final demand, which in turn modifies GDP and final demand, and so on and so forth until a convergence is reached.

4. An application to the China-USA 2018 trade conflict

The year 2018 has seen an increase in bilateral trade tensions between China and the USA. In January 2018, the US administration placed a 30% tariff on foreign solar panels and a 20% on washing machines. This was followed in March by tariffs of 25% on steel and 10% on aluminium. In April China responded by imposing tariffs on 128 products it imports from America. The Tit-for-Tat

escalation continued during most of the year. At the time of writing this article, some of the planned increases in bilateral tariffs had been postponed pending the outcome of negotiations regarding both the bilateral relations and the WTO multilateral trading system. But the economic uncertainty raised by this conflict was taking its toll on the world economy.

Some branches of activities were particularly targeted by either the USA or China during the 2018 conflict: Agriculture, Basic Metals, Electronics and Vehicles. For this exercise, we use the WIOD database in its November 2016 edition, with results updated at year 2014. The World Input-Output Tables (WIOT) cover 43 countries plus an aggregate for the rest of the world. Industry data are provided for 56 sectors producing goods and services. The simulation focuses on 17 countries belonging to the G20 group, or to the Asian region.¹⁹

- **Gains and losses from the bilateral conflict**

Table 13 presents the results of the simulation for two cases: USA blocks bilateral imports of Basic Metal from China and China blocks bilateral imports of motor vehicles, trailers and semi-trailers from USA. In the first case, the US manufactures of basic metal gain most. China's losses are large in monetary value, but are significantly reduced thanks to redeployment. The sectoral value added of Canada and Mexico, closely associated to the USA through a free trade agreement, register also net gains.

Table 13 Evolution of sectoral value-added following extraction and substitution, selected sectors (Mn dollar)

Note: The table shows the differences with the initial sectoral value added before trade conflict for Basic Metal (first panel) and Vehicles (second panel).

a/ Short-term effects of extraction include price effects (30% price hike on additional inputs).

b/ 100% of extracted exports of final products are redeployed to third countries, but no intermediate goods.

Source: Author's elaboration based on WIOT data

All other countries register negative spill-overs due to the Chinese exports to the US being redeployed towards third countries. Japan, who initially gained from the removal of Chinese competition on the US market, suffers large losses due to trade deflection. This redeployment in the face of trade conflict was first analysed quantitatively by Bown and Crowley (2003) in the context of the United States' use of import restrictions on Japanese exports between 1992 and 2001.

¹⁹ WIOD does not cover three of the G20 members: Argentina, Saudi Arabia and South Africa.

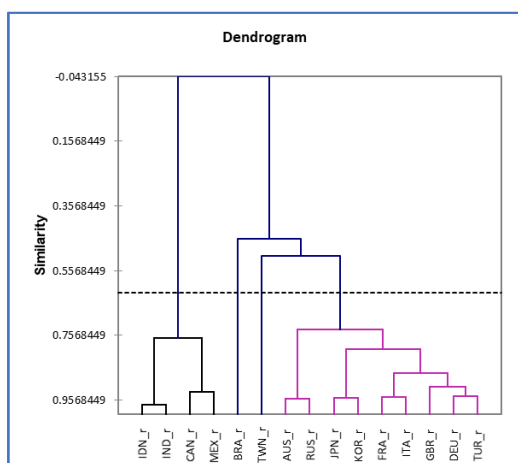

A similar pattern is observed when it is China who blocks the US imports, in this case of vehicles (second panel of Table 13). China’s automobile industry gains much from substituting US imports and US losses are mitigated thanks to the redeployment of these exports to third markets. Canada, Germany, Japan, Korea and Mexico register large losses due to the increased US competition on their domestic and export markets.

The table illustrates also the difference between an upstream sector like Basic Metal and a downstream one like Vehicles: redeploying only final products (the “Subst-FD” column) has little impact in the first case, but a large one in the second one.

- ***Further use of the extraction-cum-substitution method***

The extraction-cum-simulation method opens also the possibility of generating experimental data that can serve for further statistical analysis. Simulating a large series of bilateral shocks using the computational algorithm in Annex produces numerical results that are dependent on the mode of international insertion of countries and allows building an analytical database.

Figure 6 Agglomerative hierarchical clustering based on the similarity of sectoral response to bilateral China-USA shocks

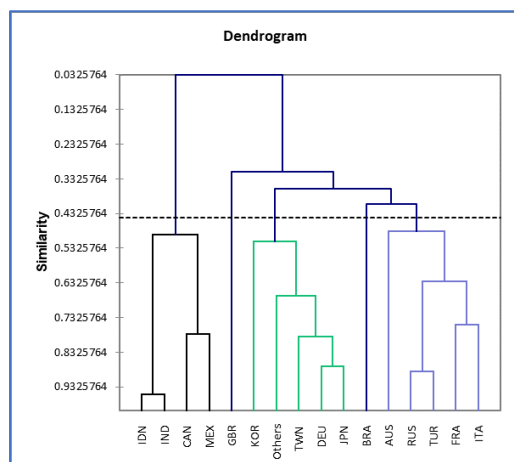

Note: Similarity is based on the Pearson coefficient of correlations calculated on the relative variation of sectoral value-added following a trade shock affecting sectoral trade between China and the USA.

Figure 6 shows the results of analysing the similarities between the countries using agglomerative hierarchical clustering (AHC). Data are based on the results of a series of bilateral shocks affecting 12 good producing sectors. For each sector, two extraction-cum-substitution were simulated, when the shock to the initial situation emanates from China and when it emanates from the USA, giving a total of 24 simulations. The statistical analysis is based on the relative variation of the sectoral value added for the following four scenarios: extraction and substitution effects in the Short and Long term; redeployment of 100% of the extracted final goods only and of 100% of the total extracted exports.

Brazil and Taiwan appear to stand out as special cases while, at the contrary, we observe strong similarities between India and Indonesia, Australia and Russia, both pairs showing also similarities between them. On the other side, we observed close similarities between Japan and Korea, France and Italy, and Germany and Turkey, joined also by the UK.

The same type of analysis can be extended to the effect of the same series of sectoral shocks on the whole GDP, and not only on the respective industries. The nature and extent of the impacts differ when considering only the sectors (Figure 6) or when looking at the overall influence on the whole economy (Figure 7). This is due to differences in (i) the nature of inter-industrial linkages and (ii) the relative weight of services sectors (the bilateral trade shocks affecting only good-producing industries). We still have strong similarities between India and Indonesia, or between France and Italy. But Germany and Japan are now close together and joined by Taiwan. At the contrary, UK and Brazil stand alone are outsiders.

Figure 7 Agglomerative hierarchical clustering based on the similarity of GDP response to bilateral China-USA shocks

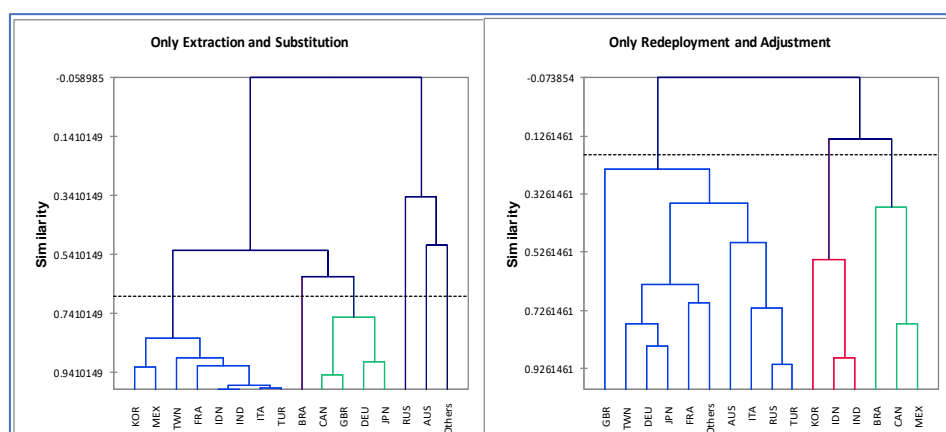

Note: Note: Similarity is based on the Pearson coefficient of correlations calculated on the relative variation of Gross Domestic Product following a trade shock affecting sectoral trade between China and the USA. “Others” denotes the other countries included in WIOT plus the ROW aggregate.

These results are only provided as example of the potential of the methodology to map the reaction of several economies to trade shocks. The similarities and dissimilarities in economic responses could be further analysed by crossing the various sectoral and global results, and correlating them with other indicators related to the structure of the economies and their trade integration.

The data generated by the method can also be used to characterise countries’ mode of World trade insertion by analysing separately the implications of successive scenarios on the third countries indirectly affected by the bilateral conflict. For example, Figure 8 splits the previous AHC analysis into two successive steps: first, the extraction of Chinese or US imports and the short- and long-term effects of their substitution in the protectionist market, then the redeployment of extracted exports to third markets and the impact on final demand. The first panel (Extraction and Substitution only) will mainly segregate countries according to their commercial presence in China or in the USA. The second panel will look at their vulnerability to an increased competition from China or the USA on their other markets. Understanding the differences in classification would require looking more in details into sectoral characteristics, and is beyond the scope of this paper. Our aim was only to show the analytical potential of the methodology.

Figure 8 Agglomerative hierarchical clustering based on the similarity of GDP response to successive phases of the bilateral China-USA trade shocks

Note: see Figure 7

5. Conclusions

This introductory paper presents a simple yet powerful methodological tool for analysing the impact of a bilateral trade conflict on third countries when trade includes intermediate inputs. Mixing input-output modelling with recent development of trade in value-added analysis, the extraction-cum-substitution approach maps and measures the sectoral and global interactions that are caused by vertical integration and global value chains.

The method is voluntarily kept as simple as possible, following the KISS principle of model building. It remains descriptive, or better say, exploratory. But it is not simplistic: it generates a rich collection of results that shows the complexity of the inter-actions and their economic relevance when the countries involved in a trade war are two large economies. When the country that is targeted in the bilateral conflict is a large and competitive exporter closely inserted in global value chains, the depth of the spill-over effects on third countries may be larger than the direct impacts on the two trade belligerents. These impacts would not be easily identified using standard input-output or network analysis. Finally, the method can be used for more general statistical analysis, besides the study of trade conflicts. The way industries in different countries react to extraction, then to substitution, provides important information on their mode of insertion in the global economy. By running a large set of simulations covering several industries and several “conflictual” pairs of trade partners, it is possible for the analyst to generate a large sample of data that provide a comprehensive and multidimensional set of indicators. Because the methodology is relatively straightforward, it does not require complex programming and can be easily iterated to generate “big data”. Then, the resulting set of indicators can be analysed through exploratory data analysis to reveal similarities between countries, or singularities.

This said, this method has limitations and should not be used for making forecasting or predictions. The main caveats that limit its use from an economic modelling perspective is the substitutability assumption, on the one hand, and the hypothesis that income and prices remain constant on the other hand. In particular, substitution ignore the gains from trade from the consumers’ perspective. Even when looking at the producer side, the surplus in the protected country (as measured by value-added

per unit of output) is reduced only in the short time. Moreover, the method does not contemplate a situation where the conflict would disrupt an entire supply chain, resulting in the bankruptcy of the firms most dependents of the extracted inputs. As a result, trade disruption in our methodology always results in a net gain for the protectionist country, something that contradicts both theory and practice. For this reason, we recommend to use the method only for what it was developed: measuring the spillover effects on third countries rather than estimating the impact on the two belligerents.

In brief, the method does not pretend to look at the deeper economic implications. In this respect, it should be interpreted as a first step before applying fully fledged economic models. Actually, the complexity is in the data and not in the methodology, and this complexity reflects the depth and variety of inter-industry interrelations in the global economy. By providing a mapping of the deep structure of inter-industrial interactions at the time of the trade shock, the method helps the analysts to understand the results of more sophisticated economic models.

Its application to a real-case bilateral trade conflict opposing China and the USA in 2018 confirms the importance of the direct and indirect spill-over effects. Trade deflection (the redeployment of exports when a large market is blockaded) inflicts potentially large losses to third countries and would probably induce them to take their own protectionist measures to shield their industries from the increased trade competition. The end-result would prove disastrous for the multilateral trade governance, mimicking the spiralling protectionism that followed the Smoot-Hawley Tariff Act in 1930, which raised U.S. tariffs on over 20,000 imported goods to record levels and was reciprocated by many countries, deepening the global recession.

1. Further discussion on the gravity equation used for substitution

The standard gravity Equation 12 used for substitution means that, when a product s is excluded from a market r , the previous exports of s to r are redistributed between the other countries that were

already present on this market in proportion to their existing market shares. The ratio of the new bilateral economic distance d'_{ar} and d'_{ir} remains also constant for a and $i \neq s$ while $d'_{sr} \rightarrow \infty$ for gross trade flows because trade costs became prohibitive under the extraction hypothesis. When considering trade in value-added, the bilateral distance d'_{sr} is still much higher than d_{sr} but s is still able to indirectly export domestic value added to s through the global value chain.

The above-mentioned extraction-cum-substitution can be considered as a special case of 'Iterative Proportional Fitting', better known in input-output analysis as RAS (the meaning of the RAS acronym is unknown). The RAS method is used in a situation when only row and column sums of desired input-output table are known. The table is then estimated from an older fully-known input-output table in a way that the resulting table is consistent with given row and column sums. Mathematically, RAS is an iterative scaling method whereby a non-negative matrix is adjusted until its column sums and row sums equal to some pre-specified totals.

In a typical RAS, each entry in one row is multiplied by a scalar that is chosen in such a way that the sum of all entries in the row or column becomes equal to its target total. Then, the same method is used to make the columns consistent with their required totals. As a result, the constraints on the row totals is not satisfied anymore. So, the algorithm repeats itself on rows and columns until resulting matrix is consistent with all required row and column totals. The adjustment of the entries of the matrix is iterative and proportional to the row and column totals.

Our case differs from a typical RAS because the adjustment starts from a pre-defined shock (extraction) and redistributes the missing trade across rows and columns in such a way that (i) the sum of rows and columns remain constant and (ii) the new coefficients of unextracted columns are related to the old ones in proportion to their initial market shares. Our algorithm assigns final demand on the basis of transactions and input-output on the basis of technical coefficients. (Dietzenbacher and Miller, 2009) prove that, under some conditions that are fulfilled in a typical input-output matrix, the rescaling vectors are unique;²⁰ updating the transactions matrix or the corresponding coefficients matrix yields the same results.

Yet, as mentioned previously, recent developments in the micro-foundations of gravity (Anderson and van Wincoop, 2003) show the bilateral relation does not depend only on the bilateral distance but also of a multilateral resistance terms (MRT), which captures general equilibrium forces. Extracting a market modifies both the bilateral and the multilateral resistance terms, especially if, as in our substitution hypothesis, the extracted industry makes extra efforts to reassign the missing trade to other markets. This is one of the reasons to restrict our method to analysing partial equilibrium simulations.

It should ideally be limited to small deviations from the general equilibrium solution (the one observed in the initial input-output matrix). But, by definition, the extraction method that is the building block of our approach is far from being a marginal variation. This explains why the method

²⁰ Property 1) under the following condition: (i) Z is a square matrix (i.e. each country is recorded both as an importer and an exporter); (ii) its diagonal elements are strictly positive (i.e. every country trades with itself); (iii) it is not block diagonal (or cannot be made block diagonal by permutations of its rows and columns, i.e. there is no group of countries operating in complete autarky).

should be considered as exploratory only, amplifying the contrast in order to provide a better mapping of underlying inter-industry relationships in third-countries. It is to forecasting what caricature is to photography: a way to amplify the most distinguishing aspects of a portrait.

2. R program

When discussing the pro and cons of the KISS principle, it is often mentioned that C. Chapman, the founder of Lotus Cars, urged his designers to "Simplify, then add lightness". I am afraid the R program that I wrote is neither simple nor light. Its clumsiness is entirely due to my almost complete ignorance of R programming when I started this work. My sole ambition here was to have something that was working and was relatively free of bugs. I cross-checked the results on small examples, but there is no guaranty at all the script is without errors. Sure, some must be remaining, thanks to Mr Murphy's Law. So, use it at your own risks and improve it.
